## 11 — Abstract —

12 First-order model counting (FOMC) is the problem of counting the number of models of a sentence in  
13 first-order logic. Since lifted inference techniques rely on reductions to variants of FOMC, the design  
14 of scalable methods for FOMC has attracted attention from both theoreticians and practitioners over  
15 the past decade. Recently, a new approach based on first-order knowledge compilation was proposed.  
16 This approach, called CRANE, instead of simply providing the final count, generates definitions of  
17 (possibly recursive) functions that can be evaluated with different arguments to compute the model  
18 count for any domain size. However, this approach is not fully automated, as it requires manual  
19 evaluation of the constructed functions. The primary contribution of this work is a fully automated  
20 compilation algorithm, called GANTRY, which transforms the function definitions into C++ code  
21 equipped with arbitrary-precision arithmetic. These additions allow the new FOMC algorithm to  
22 scale to domain sizes over 500,000 times larger than the current state of the art, as demonstrated  
23 through experimental results.

24 **2012 ACM Subject Classification** Theory of computation → Automated reasoning; Theory of  
25 computation → Logic and verification; Mathematics of computing → Combinatorics

26 **Keywords and phrases** first-order model counting, knowledge compilation, lifted inference

27 **Funding** This research was funded in part by the Natural Sciences and Engineering Research Council  
28 of Canada (NSERC), funding reference number RGPIN-2024-05956, and the Digital Research  
29 Alliance of Canada ([alliancecan.ca](https://alliancecan.ca)).

30 **Acknowledgements** The first two authors contributed equally. Part of the research was conducted  
31 while all authors were at the National University of Singapore.

For the entire paper:

- Sentence vs formula: be consistent and not confusing
- 15 pages excluding references
- Make sure all the internal references (e.g., to examples) are still valid
- Maybe add extra references to subsections
- When submitting: go through the rest of formatting instructions (in GTD)

32

## 1 Introduction

- We would like to clarify that the main contribution of this work consists of everything needed to complement recursive function definitions with the necessary base cases. This process includes identifying the base cases and their corresponding formulas, transforming them (including applying a new smoothing procedure), and recursively reusing Crane. C++ code generation, although relatively straightforward, is crucial for the usability of the algorithm.
- Focus more on current work

*First-order model counting* (FOMC) is the task of determining the number of models for a sentence in first-order logic over a specified domain. The weighted variant, WFOMC, computes the total weight of these models, linking logical reasoning with probabilistic frameworks [30]. It builds upon earlier efforts in weighted model counting for propositional logic [4] and broader attempts to bridge logic and probability [14, 16, 19]. WFOMC is central to *lifted inference*, which enhances the efficiency of probabilistic calculations by exploiting symmetries [11]. Lifted inference continues to advance, with applications extending to constraint satisfaction problems [24] and probabilistic answer set programming [1]. Moreover, WFOMC has proven effective at reasoning over probabilistic databases [8] and probabilistic logic programs [17]. FOMC algorithms have also facilitated breakthroughs in discovering integer sequences [21] and developing recurrence relations for these sequences [6]. Recently, these algorithms have been extended to perform sampling tasks [31].

The complexity of FOMC is generally measured by *data complexity*, with a formula classified as *liftable* if it can be solved in polynomial time relative to the domain size [10]. While all formulas with up to two variables are known to be liftable [27, 29], Beame et al. [3] demonstrated that liftability does not extend to all formulas, identifying an unliftable formula with three variables. Recent work has further extended the liftable fragment with additional axioms [22, 26] and counting quantifiers [12], expanding our understanding of liftability.

FOMC algorithms are diverse, with approaches ranging from *first-order knowledge compilation* (FOKC) to cell enumeration [25], local search [15], and Monte Carlo sampling [7]. Among these, FOKC-based algorithms are particularly prominent, transforming formulas into structured representations such as circuits or graphs. Even when multiple algorithms are able to solve the same instance, FOKC algorithms are known to find polynomial-time solutions, where the polynomial has a lower degree compared to other approaches [6]. The recently developed ability of a FOKC algorithm to formulate solutions in terms of recursive functions [6] is also noteworthy as the only other proposed alternative is to guess recursive relations [2]. Notable examples of FOKC algorithms include FORCLIFT [30] and its successor CRANE [6].

The CRANE algorithm marked a significant step forward, expanding the range of formulas handled by FOMC algorithms. However, it had notable limitations: it required manual evaluation of function definitions to compute model counts and introduced recursive functions without proper base cases, making it more complex to use. To address these shortcomings, we present GANTRY, a fully automated FOMC algorithm that overcomes the constraints of its predecessor. GANTRY can handle domain sizes over 500,000 times larger than previous algorithms and simplifies the user experience by automatically handling base cases and compiling function definitions into efficient C++ programs.

In Section 2, we cover some preliminaries, and in Section 3, we detail all our technical contributions. Finally, in Section 4, we present our experimental results, demonstrating GANTRY’s performance compared to other FOMC algorithms, and, in Section 5, we conclude

74 the paper by discussing promising avenues for future work.

## 75 2 Preliminaries

- If I need more space elsewhere, shortening the preliminaries to two pages (perhaps skipping Section 2.2 altogether?)
- Adjust the introductory paragraph below to the new structure (with more subsections)

76  
77 In Section 2.1, we summarise the basic principles of first-order logic. Then, in Appendix A,  
78 we formally define (W)FOMC and discuss the distinctions between three variations of first-  
79 order logic used for FOMC. Finally, in Section 2.4, we introduce the terminology used to  
80 describe the output of the original CRANE algorithm, i.e., functions and equations that define  
81 them.

### 82 Notation

83 We use  $\mathbb{N}_0$  to represent the set of non-negative integers. In both algebra and logic, we write  
84  $S\sigma$  to denote the application of a *substitution*  $\sigma$  to an expression  $S$ , where  $\sigma = [x_1 \mapsto y_1, x_2 \mapsto$   
85  $y_2, \dots, x_n \mapsto y_n]$  signifies the replacement of all instances of  $x_i$  with  $y_i$  for all  $i = 1, \dots, n$ .

86 Additionally, for any variable  $n$  and  $a, b \in \mathbb{N}_0$ , let  $[a \leq n \leq b] := \begin{cases} 1 & \text{if } a \leq n \leq b \\ 0 & \text{otherwise} \end{cases}$ .

### 87 2.1 First-Order Logic

88 In this section, we will review the basic concepts of first-order logic as they are used in  
89 FOMC algorithms. We begin by introducing the format used internally by FORCLIFT and its  
90 descendants. Afterwards, we provide a high-level description of how an arbitrary sentence in  
91 first-order logic is transformed into this internal format.

92 A *term* can be either a variable or a constant. An *atom* can be either  $P(t_1, \dots, t_m)$  (i.e.,  
93  $P(\mathbf{t})$ ) for some predicate  $P$  and terms  $t_1, \dots, t_m$  or  $x = y$  for some terms  $x$  and  $y$ . The  
94 *arity* of a predicate is the number of arguments it takes, i.e.,  $m$  in the case of the predicate  
95  $P$  mentioned above. We write  $P/m$  to denote a predicate along with its arity. A *literal*  
96 can be either an atom (i.e., a *positive* literal) or its negation (i.e., a *negative* literal). An  
97 atom is *ground* if it contains no variables, i.e., only constants. A *clause* is of the form  
98  $\forall x_1 \in \Delta_1. \forall x_2 \in \Delta_2 \dots \forall x_n \in \Delta_n. \phi(x_1, x_2, \dots, x_n)$ , where  $\phi$  is a disjunction of literals that  
99 only contain variables  $x_1, \dots, x_n$  (and any constants). We say that a clause is a (*positive*)  
100 *unit clause* if there is only one literal with a predicate, and it is a positive literal. Finally, a  
101 *formula* is a conjunction of clauses. Throughout the paper, we will use set-theoretic notation,  
102 interpreting a formula as a set of clauses and a clause as a set of literals.

103 ► **Remark.** Conforming with previous work [30], the definition of a clause includes universal  
104 quantifiers for all variables within. While it is possible to rewrite the entire formula with all  
105 quantifiers at the front [9], the format we describe has proven itself convenient to work with.

### 106 2.2 First-Order Model Counting

107 In this section, we will formally define FOMC and its weighted variant. Note that, although  
108 this work focuses on FOMC, for sentences with existential quantifiers, computing the FOMC  
109 using GANTRY requires the use of WFOMC. For such sentences, preprocessing (described in

Section 2.3) introduces predicates with non-unary weights that must be accounted for to compute the correct model count.

► **Definition 1** (Structure, model). *Let  $\phi$  be a formula in FO. For each predicate  $P/n$  in  $\phi$ , let  $(\Delta_i^P)_{i=1}^n$  be a list of the corresponding domains. Let  $\sigma$  be a map from the domains of  $\phi$  to their interpretations as finite sets such that the sets are pairwise disjoint, and the constants in  $\phi$  are included in the corresponding domains. A structure of  $\phi$  is a set  $M$  of ground literals defined by adding to  $M$  either  $P(\mathbf{t})$  or  $\neg P(\mathbf{t})$  for every predicate  $P/n$  in  $\phi$  and  $n$ -tuple  $\mathbf{t} \in \prod_{i=1}^n \sigma(\Delta_i^P)$ . A structure is a model if it makes  $\phi$  valid.*

► **Example 2** (Counting bijections). Let us consider the following formula (previously examined by Dilkas and Belle [6]) that defines predicate  $P$  as a bijection between two domains  $\Gamma$  and  $\Delta$ :

$$\begin{aligned} & (\forall x \in \Gamma. \exists y \in \Delta. P(x, y)) \wedge \\ & (\forall y \in \Delta. \exists x \in \Gamma. P(x, y)) \wedge \\ & (\forall x \in \Gamma. \forall y, z \in \Delta. P(x, y) \wedge P(x, z) \Rightarrow y = z) \wedge \\ & (\forall x, z \in \Gamma. \forall y \in \Delta. P(x, y) \wedge P(z, y) \Rightarrow x = z). \end{aligned} \tag{1}$$

Let  $\sigma$  be defined as  $\sigma(\Gamma) := \{1, 2\}$ , and  $\sigma(\Delta) := \{a, b\}$ . Then Formula (1) has two models:

$$\{P(1, a), P(2, b), \neg P(1, b), \neg P(2, a)\} \quad \text{and} \quad \{P(1, b), P(2, a), \neg P(1, a), \neg P(2, b)\}.$$

► **Remark.** The distinctness of domains is important in two ways. First, in terms of expressiveness, a clause such as  $\forall x \in \Delta. P(x, x)$  is valid if predicate  $P$  is defined over two copies of the same domain and invalid otherwise. Second, having more distinct domains makes the problem more decomposable for the FOKC algorithm. With distinct domains, the algorithm can make assumptions or deductions about, e.g., the first domain of predicate  $P$  without worrying how (or if) they apply to the second domain.

► **Definition 3** (WFOMC instance). *A WFOMC instance comprises: a formula  $\phi$  in FO, two (rational) weights  $w^+(P)$  and  $w^-(P)$  assigned to each predicate  $P$  in  $\phi$ , and  $\sigma$  as described in Definition 1. Unless specified otherwise, we assume all weights to be equal to 1.*

► **Definition 4** (WFOMC [30]). *Given a WFOMC instance  $(\phi, w^+, w^-, \sigma)$  as in Definition 3, the (symmetric) weighted first-order model count (WFOMC) of  $\phi$  is*

$$\sum_{M \models \phi} \prod_{P(\mathbf{t}) \in M} w^+(P) \prod_{\neg P(\mathbf{t}) \in M} w^-(P), \tag{2}$$

where the sum is over all models of  $\phi$ .

## 2.3 Crane and First-Order Knowledge Compilation

As our work builds on CRANE, in this section we will briefly outline the steps CRANE goes through to compile an FO formula into a set of function definitions. We divide the inner workings of the algorithm into two stages: preprocessing and compilation.

### 2.3.1 Preprocessing

The goal of this stage is to transform an arbitrary FO formula into the format described in Section 2.1, most importantly by eliminating existential quantifiers. For example, the first conjunct of Formula (1), i.e.,

$$\forall x \in \Gamma. \exists y \in \Delta. P(x, y) \tag{3}$$

146 is transformed into

$$\begin{aligned}
 & (\forall x \in \Gamma. Z(x)) \wedge \\
 & (\forall x \in \Gamma. \forall y \in \Delta. Z(x) \vee \neg P(x, y)) \wedge \\
 & (\forall x \in \Gamma. S(x) \vee Z(x)) \wedge \\
 & (\forall x \in \Gamma. \forall y \in \Delta. S(x) \vee \neg P(x, y)),
 \end{aligned} \tag{4}$$

148 where  $Z/1$  and  $S/1$  are two new predicates with  $w^-(S) = -1$ . One can check that the  
 149 WFOMC of Formulas (3) and (4) is the same.

### 150 2.3.2 Compilation

151 At this stage, the preprocessed formula is compiled into the set  $\mathcal{E}$  of equations and two  
 152 auxiliary maps  $\mathcal{F}$  and  $\mathcal{D}$ .  $\mathcal{F}$  maps function names to formulas, and  $\mathcal{D}$  maps function names  
 153 and argument indices to domains.  $\mathcal{E}$  can contain any number of functions, one of which  
 154 (which we will always denote by  $f$ ) represents the solution to the FOMC problem. To  
 155 compute the FOMC for particular domain sizes,  $f$  must be evaluated with those domain  
 156 sizes as arguments.  $\mathcal{D}$  records this correspondence between function arguments and domains.

157 ► **Example 5.** CRANE compiles Formula (1) for bijection counting into

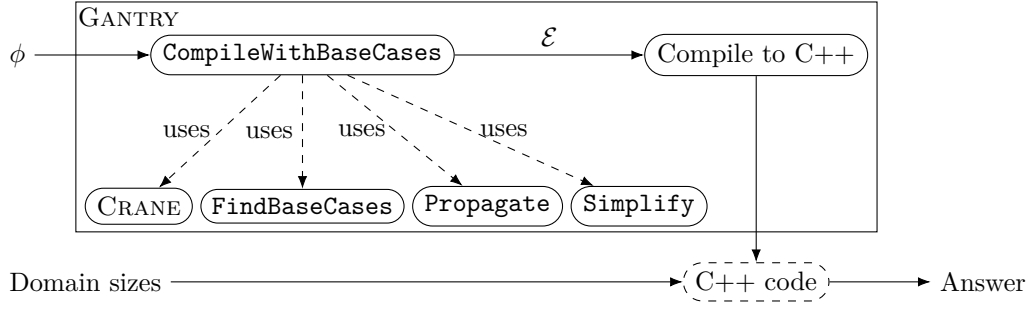

$$\begin{aligned}
 \mathcal{E} &= \left\{ \begin{aligned} f(m, n) &= \sum_{l=0}^n \binom{n}{l} (-1)^{n-l} g(l, m), \\ g(l, m) &= \sum_{k=0}^m [0 \leq k \leq 1] \binom{m}{k} g(l-1, m-k) \end{aligned} \right\}; \\
 \mathcal{D} &= \{ (f, 1) \mapsto \Gamma, (f, 2) \mapsto \Delta, (g, 1) \mapsto \Delta^\top, (g, 2) \mapsto \Gamma \},
 \end{aligned}$$

160 where  $\Delta^\top$  is a newly introduced domain. (We omit the definition of  $\mathcal{F}$  as the formulas can  
 161 get quite verbose.) To compute the number of bijections between two sets of cardinality  
 162 3, one would evaluate  $f(3, 3)$ , however, the definition of  $g$  is incomplete:  $g$  is a recursive  
 163 function presented without any base cases.  $\mathcal{D}$  encodes that in  $f(m, n)$ ,  $m$  and  $n$  represent  
 164  $|\Gamma|$  and  $|\Delta|$ , respectively. Similarly, in  $g(l, m)$ ,  $l$  represents  $|\Delta^\top|$ , and  $m$  represents  $|\Gamma|$ .

165 Compilation is performed primarily by applying (*compilation*) rules to formulas. CRANE  
 166 has two modes depending on how the algorithm chooses which compilation rule to apply to  
 167 a formula (in case several alternatives are available). The first option is to use greedy search:  
 168 there is a list of rules, and the first applicable rule is the one that gets used, disregarding  
 169 all the others. The second option is to use a combination of greedy and *breadth-first search*  
 170 (BFS). That is, each compilation rule is identified as either greedy or non-greedy. Greedy  
 171 rules are applied as soon as possible at any stage of the compilation process. BFS is executed  
 172 over all applicable non-greedy rules, identifying the solution that can be constructed using  
 173 the smallest number of such rules.

## 174 2.4 Algebra

175 In this paper, we use both logical and algebraic constructs. While the rest of Section 2 focused  
 176 on the former, this section describes the latter. We write **expr** for an arbitrary algebraic  
 177 expression. In the context of algebra, a *constant* is a non-negative integer. Likewise, a  
 178 *variable* can either be a parameter of a function or a variable introduced through summation,  
 179 such as  $i$  in the expression  $\sum_{i=1}^n \mathbf{expr}$ . A *function call* is  $f(x_1, \dots, x_n)$  (or  $f(\mathbf{x})$  for short),

■ **Figure 1** The outline of using GANTRY to compute the model count of a formula  $\phi$ . First, the formula is compiled into a set of equations, which are then used to create a C++ program. This program can be executed with different command line arguments to calculate the model count of  $\phi$  for different domain sizes. To accomplish this, the `CompileWithBaseCases` procedure uses CRANE, algebraic simplification techniques (denoted as `Simplify`), and two other auxiliary procedures.

180 where  $f$  is an  $n$ -ary function, and each  $x_i$  is an algebraic expression consisting of variables  
 181 and constants. A (function) *signature* is function call that contains only variables. Given two  
 182 function calls  $f(\mathbf{x})$  and  $f(\mathbf{y})$ , we say that  $f(\mathbf{y})$  *matches*  $f(\mathbf{x})$  if  $x_i = y_i$  whenever  $x_i, y_i \in \mathbb{N}_0$ .  
 183 An *equation* is  $f(\mathbf{x}) = \text{expr}$ , where  $f(\mathbf{x})$  is a function call.

184 ► **Definition 6** (Base case). Let  $f(\mathbf{x})$  be a function call where each  $x_i$  is either a constant  
 185 or a variable. Then function call  $f(\mathbf{y})$  is a base case of  $f(\mathbf{x})$  if  $f(\mathbf{y}) = f(\mathbf{x})\sigma$ , where  $\sigma$  is a  
 186 substitution that replaces one or more  $x_i$  with a constant.

187 ► **Example 7.** In equation  $f(m, n) = f(m - 1, n) + nf(m - 1, n - 1)$ , the only constant is  
 188 1, and the variables are  $m$  and  $n$ . The equation contains three function calls: one on the  
 189 left-hand side (LHS), and two on the right-hand side (RHS). The function call on the LHS  
 190 is a signature. Function calls such as  $f(4, n)$ ,  $f(m, 0)$ , and  $f(8, 1)$  are all considered base cases  
 191 of  $f(m, n)$  (only some of which are useful).

### 192 3 Technical Contributions

193 Figure 1 provides an overview of GANTRY’s workflow. Below we briefly describe and motivate  
 194 each procedure before going into more detail in the corresponding subsection.

195 `CompileWithBaseCases` (see Section 3.1), the core procedure of GANTRY, is responsible  
 196 for completing the function definitions produced by CRANE with the necessary base cases.  
 197 To do so, it may recursively call itself (and CRANE) on other formulas. We prove that the  
 198 number of such recursive calls is upper bounded by the number of domains in the formula.

199 Section 3.1 also describes the `Simplify` procedure for algebraic simplification. It is crucial  
 200 for simplifying, e.g., a sum of  $n$  terms, only two of which are non-zero. More generally, the  
 201 equations returned by CRANE often benefit from easy-to-detect algebraic simplifications such  
 202 as  $0 \cdot \text{anything} = 0$  and  $\text{anything}^0 = 1$ .

203 `FindBaseCases` (described in Section 3.2) inspects a set of equations to identify a sufficient  
 204 set of base cases for a given set of equations. We prove that the returned set of base cases is  
 205 sufficient, and the evaluation of the resulting function definitions will never get stuck in an  
 206 infinite loop.

207 Section 3.3 introduces the `Propagate` procedure that takes a formula  $\phi$ , a domain  $\Delta$ ,  
 208 and  $n \in \mathbb{N}_0$ . It returns  $\phi$  transformed with the assumption that  $|\Delta| = n$ , introducing  $n$  new  
 209 constants and removing all variables quantified over  $\Delta$ . For example, when computing a

---

**Algorithm 1** `CompileWithBaseCases( $\phi$ )

---`

**Input:** formula  $\phi$   
**Output:** set  $\mathcal{E}$  of equations  
1  $(\mathcal{E}, \mathcal{F}, \mathcal{D}) \leftarrow \text{CRANE}(\phi);$   
2  $\mathcal{E} \leftarrow \text{Simplify}(\mathcal{E});$   
3 **foreach** *base case*  $f(\mathbf{x}) \in \text{FindBaseCases}(\mathcal{E})$  **do**  
4      $\psi \leftarrow \mathcal{F}(f);$   
5     **foreach** *index*  $i$  *such that*  $x_i \in \mathbb{N}_0$  **do**  $\psi \leftarrow \text{Propagate}(\psi, \mathcal{D}(f, i), x_i);$   
6      $\mathcal{E} \leftarrow \mathcal{E} \cup \text{CompileWithBaseCases}(\psi);$

---

base case such as  $f(0, y)$ , `Propagate` will significantly simplify  $\phi$  with the assumption that the domain associated with the first parameter of  $f$  (i.e.,  $\mathcal{D}(f, 1)$ ) is empty. When run on this simplified formula, `CompileWithBaseCases` will return the equations for the base case  $f(0, y)$ .

Section 3.4 describes a new kind of *smoothing* used to ensure that `Propagate` preserves the correct model count. Smoothing is a well-known technique in knowledge compilation algorithms for propositional model counting [5]. Although it has been applied to FOMC before [30], our setting requires a novel approach.

`CompileWithBaseCases`, together with the other procedures outlined above, return a set of equations that fully cover the base cases of all recursive functions. While these equations can be interesting and valuable in their own right, the users of FOMC algorithms typically expect a numerical answer. Thus, Section 3.5 describes how these equations are compiled into a C++ program that can be executed with different command-line arguments to compute the model count for different combinations of domain sizes.

### 3.1 Completing the Definitions of Functions

Algorithm 1 presents our overall approach for compiling a formula into equations that include the necessary base cases. To begin, we use `CRANE` to compile the formula into the three components:  $\mathcal{E}$ ,  $\mathcal{F}$ , and  $\mathcal{D}$  (as described in Section 2.3.2). After some algebraic simplifications (described below),  $\mathcal{E}$  is passed to the `FindBaseCases` procedure (see Section 3.2). For each base case  $f(\mathbf{x})$ , we retrieve the logical formula  $\mathcal{F}(f)$  associated with the function name  $f$  and simplify it using the `Propagate` procedure (explained in detail in Section 3.3). We do this by iterating over all indices of  $\mathbf{x}$ , where  $x_i$  is a constant, and using `Propagate` to simplify  $\psi$  by assuming that domain  $\mathcal{D}(f, i)$  has size  $x_i$ . Finally, on line 6, `CompileWithBaseCases` recurses on these simplified formulas and adds the resulting base case equations to  $\mathcal{E}$ .

#### Simplify

The main responsibility of the `Simplify` procedure is to handle the algebraic pattern  $\sum_{m=0}^n [a \leq m \leq b] f(m)$ . Here:  $n$  is a variable,  $a, b \in \mathbb{N}_0$  are constants, and  $f$  is an expression that may depend on  $m$ . `Simplify` transforms this pattern into  $f(a) + f(a+1) + \dots + f(\min\{n, b\})$ .

► **Example 8.** Let us return to the bijection-counting problem from Example 2 and its initial solution described in Example 5. `Simplify` transforms  $g(l, m) = \sum_{k=0}^m [0 \leq k \leq 1] \binom{m}{k} g(l-1, m-k)$  into  $g(l, m) = g(l-1, m) + mg(l-1, m-1)$ . Then `FindBaseCases` identifies two base cases:  $g(0, m)$  and  $g(l, 0)$ . In both cases, `CompileWithBaseCases` recurses

---

**Algorithm 2** FindBaseCases( $\mathcal{E}$ )

---

**Input:** set  $\mathcal{E}$  of equations  
**Output:** set  $\mathcal{B}$  of base cases  
1  $\mathcal{B} \leftarrow \emptyset$ ;  
2 **foreach** function call  $f(\mathbf{y})$  on the RHS of an equation in  $\mathcal{E}$  **do**  
3      $\mathbf{x} \leftarrow$  the parameters of  $f$  in its definition;  
4     **foreach**  $y_i \in \mathbf{y}$  **do**  
5         **if**  $y_i \in \mathbb{N}_0$  **then**  $\mathcal{B} \leftarrow \mathcal{B} \cup \{f(\mathbf{x})[x_i \mapsto y_i]\}$ ;  
6         **else if**  $y_i = x_i - c_i$  for some  $c_i \in \mathbb{N}_0$  **then**  
7             **for**  $j \leftarrow 0$  **to**  $c_i - 1$  **do**  $\mathcal{B} \leftarrow \mathcal{B} \cup \{f(\mathbf{x})[x_i \mapsto j]\}$ ;

---

243 on the formula  $\mathcal{F}(g)$  simplified by assuming that one of the domains is empty. In the first  
244 case, we recurse on the formula  $\forall x \in \Gamma. S(x) \vee \neg S(x)$ , where  $S$  is a predicate introduced by  
245 preprocessing with weights  $w^+(S) = 1$  and  $w^-(S) = -1$ . Hence, we obtain the base case  
246  $g(0, m) = 0^m$ . In the case of  $g(l, 0)$ , **Propagate**( $\psi, \Gamma, 0$ ) returns an empty formula, resulting  
247 in  $g(l, 0) = 1$ . While these base cases overlap when  $l = m = 0$ , they remain consistent since  
248  $0^0 = 1$ .

249 We end this section by proving that **CompileWithBaseCases** terminates since each  
250 recursive call on line 6 reduces the number of domains in the formula.

251 **► Theorem 9.** *Given any FO formula  $\phi$ , **CompileWithBaseCases**( $\phi$ ) terminates.*

252 To prove the theorem, we rely on two observations about the algorithms presented in  
253 Sections 3.2 and 3.3.

254 **► Observation 10.** *Each base case returned by **FindBaseCases** has at least one constant (in*  
255 *line with Definition 6).*

256 **► Observation 11.** *For any formula  $\phi$ , domain  $\Delta$ , and  $n \in \mathbb{N}_0$ , **Propagate**( $\phi, \Delta, n$ ) returns*  
257 *a formula with no variables quantified over  $\Delta$ .*

258 **Proof.** We proceed by induction on the number of domains that variables in  $\phi$  are quantified  
259 over. If there are no domains, then  $\phi$  is essentially a propositional formula, and **CRANE**  
260 compiles it into an equation of the form  $f = \text{expr}$  with no ‘function calls’. Suppose that  
261 **CompileWithBaseCases** terminates for all formulas with at most  $n \in \mathbb{N}_0$  domains. Let  $\phi$  be  
262 a formula with  $n + 1$  domains. By Observation 10, each base case on line 3 of Algorithm 1  
263 has at least one constant. Therefore, by Observation 11, after line 5, formula  $\psi$  has at most  
264  $n$  domains. Thus, line 6 terminates by the inductive hypothesis, completing the proof that  
265 **CompileWithBaseCases** terminates for an arbitrary formula with  $n + 1$  domains. ◀

## 3.2 Identifying a Sufficient Set of Base Cases

267 Algorithm 2 summarises the implementation of **FindBaseCases**. It considers two types of  
268 arguments when a function  $f$  calls itself recursively: constants and arguments of the form  
269  $x_i - c_i$ . Here,  $c_i$  is a constant, and  $x_i$  is the  $i$ -th argument of the signature of  $f$ . When the  
270 argument is a constant  $c_i$ , a base case with  $c_i$  is added. In the second case, a base case is  
271 added for each constant from 0 up to (but not including)  $c_i$ .

272 ► **Example 12.** Consider the recursive function  $g$  from Example 5. `FindBaseCases` iterates  
 273 over two function calls:  $g(l-1, m)$  and  $g(l-1, m-1)$ . The former produces the base case  
 274  $g(0, m)$ , while the latter produces both  $g(0, m)$  and  $g(l, 0)$ .

275 It can be shown that the base cases identified by `FindBaseCases` are sufficient for the  
 276 algorithm to terminate.<sup>1</sup> For the remainder of this section, let  $\mathcal{E}$  denote the equations  
 277 returned by `CompileWithBaseCases`.

278 ► **Theorem 13.** *Let  $f$  be an  $n$ -ary function in  $\mathcal{E}$  and  $\mathbf{x} \in \mathbb{N}_0^n$ . Then the evaluation of  $f(\mathbf{x})$*   
 279 *terminates.*

280 We prove Theorem 13 using double induction. First, we apply induction to the number  
 281 of functions in  $\mathcal{E}$ . Then, we use induction on the arity of the ‘last’ function in  $\mathcal{E}$  according to  
 282 some topological ordering. We begin with a few observations that stem from previous [6, 30]  
 283 and this work.

284 ► **Observation 14.** *For each function  $f$ , there is precisely one equation  $e \in \mathcal{E}$  with  $f(\mathbf{x})$*   
 285 *on the LHS where all  $x_i$ ’s are variables (i.e.,  $e$  is not a base case). We refer to  $e$  as the*  
 286 *definition of  $f$ .*

287 ► **Observation 15.** *There is a topological ordering of all functions  $(f_i)_i$  in  $\mathcal{E}$  such that*  
 288 *equations in  $\mathcal{E}$  with  $f_i$  on the LHS do not contain function calls to  $f_j$  with  $j > i$ . This*  
 289 *condition prevents mutual recursion and other cyclic scenarios.*

290 ► **Observation 16.** *For each equation  $(f(\mathbf{x}) = \text{expr}) \in \mathcal{E}$ , the evaluation of  $\text{expr}$  terminates*  
 291 *when provided with the values of all relevant function calls.*

292 ► **Corollary 17.** *If  $f$  is a non-recursive function with no function calls on the RHS of its*  
 293 *definition, then the evaluation of any function call  $f(\mathbf{x})$  terminates.*

294 ► **Observation 18.** *For each equation  $(f(\mathbf{x}) = \text{expr}) \in \mathcal{E}$ , if  $\mathbf{x}$  contains only constants, then*  
 295  *$\text{expr}$  cannot include any function calls to  $f$ .*

296 Additionally, we introduce an assumption about the structure of recursion.

297 ► **Assumption 19.** *For each equation  $(f(\mathbf{x}) = \text{expr}) \in \mathcal{E}$ , every recursive function call*  
 298  *$f(\mathbf{y}) \in \text{expr}$  satisfies the following:*

- 299 ■ *Each  $y_i$  is either  $x_i - c_i$  or  $c_i$  for some constant  $c_i$ .*
- 300 ■ *There exists  $i$  such that  $y_i = x_i - c_i$  for some  $c_i > 0$ .*

301 Finally, we assume a particular order of evaluation for function calls using the equations  
 302 in  $\mathcal{E}$ . Specifically, we assume that base cases are considered before the recursive definition.  
 303 The exact order in which base cases are considered is immaterial.

304 ► **Assumption 20.** *When multiple equations in  $\mathcal{E}$  match a function call  $f(\mathbf{x})$ , preference is*  
 305 *given to an equation with the most constants on its LHS.*

306 With the observations and assumptions mentioned above, we are ready to prove Theo-  
 307 rem 13. For readability, we divide the proof into several lemmas of increasing generality.

---

<sup>1</sup> Note that characterising the fine-grained complexity of the solutions found by GANTRY or other FOMC algorithms is an emerging area of research. These questions have been partially addressed in previous work [6, 23] and are orthogonal to the goals of this section.

308 ► **Lemma 21.** *Assume that  $\mathcal{E}$  consists of just one unary function  $f$ . Then the evaluation of*  
 309 *a function call  $f(x)$  terminates for any  $x \in \mathbb{N}_0$ .*

310 **Proof.** If  $f(x)$  is captured by a base case, then its evaluation terminates by Corollary 17  
 311 and Observation 18. If  $f$  is not recursive, the evaluation of  $f(x)$  terminates by Corollary 17.

312 Otherwise, let  $f(y)$  be an arbitrary function call on the RHS of the definition of  $f(x)$ . If  
 313  $y$  is a constant, then there is a base case for  $f(y)$ . Otherwise, let  $y = x - c$  for some  $c > 0$ .  
 314 Then there exists  $k \in \mathbb{N}_0$  such that  $0 \leq x - kc \leq c - 1$ . So, after  $k$  iterations, the sequence of  
 315 function calls  $f(x), f(x - c), f(x - 2c), \dots$  will be captured by the base case  $f(x \bmod c)$ . ◀

316 ► **Lemma 22.** *Generalising Lemma 21, let  $\mathcal{E}$  be a set of equations for one  $n$ -ary function  $f$*   
 317 *for some  $n \geq 1$ . Then the evaluation of  $f(\mathbf{x})$  terminates for any  $\mathbf{x} \in \mathbb{N}_0^n$ .*

318 **Proof.** If  $f$  is non-recursive, the evaluation of  $f(\mathbf{x})$  terminates by previous arguments. We  
 319 proceed by induction on  $n$ , with the base case of  $n = 1$  handled by Lemma 21. Assume that  
 320  $n > 1$ . Any base case of  $f$  can be seen as a function of arity  $n - 1$ , since one of the parameters  
 321 is fixed. Thus, the evaluation of any base case terminates by the inductive hypothesis. It  
 322 remains to show that the evaluation of the recursive equation for  $f$  terminates, but that  
 323 follows from Observation 16. ◀

324 **Proof of Theorem 13.** We proceed by induction on the number of functions  $n$ . The base  
 325 case of  $n = 1$  is handled by Lemma 22. Let  $(f_i)_{i=1}^n$  be some topological ordering of these  
 326  $n > 1$  functions. If  $f = f_j$  for  $j < n$ , then the evaluation of  $f(\mathbf{x})$  terminates by the inductive  
 327 hypothesis since  $f_j$  cannot call  $f_n$  by Observation 15. Using the inductive hypothesis that  
 328 all function calls to  $f_j$  (with  $j < n$ ) terminate, the proof proceeds similarly to the Proof of  
 329 Lemma 22. ◀

### 330 3.3 Propagating Domain Size Assumptions

331 Algorithm 3, called **Propagate**, modifies the formula  $\phi$  based on the assumption that  $|\Delta| = n$ .  
 332 When  $n = 0$ , some clauses become vacuously satisfied and can be removed. When  $n > 0$ ,  
 333 partial grounding is performed by replacing all variables quantified over  $\Delta$  with constants.  
 334 (None of the formulas examined in this work had  $n > 1$ .) Algorithm 3 handles these two  
 335 cases separately. For a literal or a clause  $C$ , the set of corresponding domains is denoted as  
 336  $\text{Doms}(C)$ .

337 In the case of  $n = 0$ , there are three types of clauses to consider:

- 338 1. those that do not mention  $\Delta$ ,
- 339 2. those in which every literal contains variables quantified over  $\Delta$ , and
- 340 3. those that have some literals with variables quantified over  $\Delta$  and some without.

341 Clauses of Type 1 are transferred to the new formula  $\phi'$  without any changes. For clauses of  
 342 Type 2,  $C'$  is empty, so these clauses are filtered out. As for clauses of Type 3, a new kind of  
 343 smoothing is performed, which will be explained in Section 3.4.

344 In the case of  $n > 0$ ,  $n$  new constants are introduced. Let  $C$  be an arbitrary clause in  $\phi$ ,  
 345 and let  $m \in \mathbb{N}_0$  be the number of variables in  $C$  quantified over  $\Delta$ . If  $m = 0$ ,  $C$  is added  
 346 directly to  $\phi'$ . Otherwise, a clause is added to  $\phi'$  for every possible combination of replacing  
 347 the  $m$  variables in  $C$  with the  $n$  new constants.

348 ► **Example 23.** Let  $C \equiv \forall x \in \Gamma. \forall y, z \in \Delta. \neg P(x, y) \vee \neg P(x, z) \vee y = z$ . Then  $\text{Doms}(C) =$   
 349  $\text{Doms}(\neg P(x, y)) = \text{Doms}(\neg P(x, z)) = \{\Gamma, \Delta\}$ , and  $\text{Doms}(y = z) = \{\Delta\}$ . A call to

■ **Algorithm 3**  $\text{Propagate}(\phi, \Delta, n)$

---

**Input:** formula  $\phi$ , domain  $\Delta$ ,  $n \in \mathbb{N}_0$   
**Output:** formula  $\phi'$

```

1  $\phi' \leftarrow \emptyset$ ;
2 if  $n = 0$  then
3   foreach clause  $C \in \phi$  do
4     if  $\Delta \notin \text{Doms}(C)$  then  $\phi' \leftarrow \phi' \cup \{C\}$ ;
5     else
6        $C' \leftarrow \{l \in C \mid \Delta \notin \text{Doms}(l)\}$ ;
7       if  $C' \neq \emptyset$  then
8          $l \leftarrow$  an arbitrary literal in  $C'$ ;
9          $\phi' \leftarrow \phi' \cup \{C' \cup \{\neg l\}\}$ ;
10  else
11     $D \leftarrow$  a set of  $n$  new constants in  $\Delta$ ;
12    foreach clause  $C \in \phi$  do
13       $(x_i)_{i=1}^m \leftarrow$  the variables in  $C$  with domain  $\Delta$ ;
14      if  $m = 0$  then  $\phi' \leftarrow \phi' \cup \{C\}$ ;
15      else  $\phi' \leftarrow \phi' \cup \{C[x_1 \mapsto c_1, \dots, x_m \mapsto c_m] \mid (c_i)_{i=1}^m \in D^m\}$ ;

```

---

350  $\text{Propagate}(\{C\}, \Delta, 3)$  would result in the following formula with nine clauses:

$$\begin{aligned}
351 & (\forall x \in \Gamma. \neg P(x, c_1) \vee \neg P(x, c_1) \vee c_1 = c_1) \wedge \\
352 & (\forall x \in \Gamma. \neg P(x, c_1) \vee \neg P(x, c_2) \vee c_1 = c_2) \wedge \\
353 & \quad \vdots \\
354 & (\forall x \in \Gamma. \neg P(x, c_3) \vee \neg P(x, c_3) \vee c_3 = c_3).
\end{aligned}$$

355 Here,  $c_1$ ,  $c_2$ , and  $c_3$  are the new constants.

### 356 3.4 Smoothing the Base Cases

357 Smoothing modifies a circuit to reintroduce eliminated atoms, ensuring the correct model  
358 count [5, 30]. In this section, we describe a similar process performed on lines 7–9 of  
359 Algorithm 3. Line 7 checks if smoothing is necessary, and lines 8 and 9 execute it. If the  
360 condition on line 7 is not satisfied, the clause is not smoothed but omitted.

361 Suppose  $\text{Propagate}$  is called with arguments  $(\phi, \Delta, 0)$ , i.e., we are simplifying the formula  
362  $\phi$  by assuming that the domain  $\Delta$  is empty. Informally, if there is a predicate  $P$  in  $\phi$  unrelated  
363 to  $\Delta$ , smoothing preserves all occurrences of  $P$  even if all clauses with  $P$  become vacuously  
364 satisfied.

365 ► **Example 24.** Let  $\phi$  be

$$366 (\forall x \in \Delta. \forall y, z \in \Gamma. Q(x) \vee P(y, z)) \wedge \tag{5}$$

$$367 (\forall y, z \in \Gamma'. P(y, z)), \tag{6}$$

368 where  $\Gamma' \subseteq \Gamma$  is a domain introduced by a compilation rule. It should be noted that  $P$ , as a  
369 relation, is a subset of  $\Gamma \times \Gamma$ .

■ **Algorithm 4** A sketch of the C++ program for the equations in Example 5, particularly highlighting the recursive definition of function  $g$ .

---

```

1 initialise  $\text{Cache}_{g(0,m)}$ ,  $\text{Cache}_{g(l,0)}$ ,  $\text{Cache}_g$ , and  $\text{Cache}_f$ ;
2 Function  $g_{0,m}(m)$ : ...
3 Function  $g_{l,0}(l)$ : ...
4 Function  $g(l, m)$ :
5   if  $(l, m) \in \text{Cache}_g$  then return  $\text{Cache}_g(l, m)$ ;
6   if  $l = 0$  then return  $g_{0,m}(m)$ ;
7   if  $m = 0$  then return  $g_{l,0}(l)$ ;
8    $r \leftarrow g(l-1, m) + mg(l-1, m-1)$ ;
9    $\text{Cache}_g(l, m) \leftarrow r$ ;
10  return  $r$ ;
11 Function  $f(m, n)$ : ...
12 Function Main:
13    $(m, n) \leftarrow \text{ParseCommandLineArguments}()$ ;
14   return  $f(m, n)$ ;

```

---

Now, let us reason manually about the model count of  $\phi$  when  $\Delta = \emptyset$ . Predicate  $Q$  can only take one value,  $Q = \emptyset$ . The value of  $P$  is fixed over  $\Gamma' \times \Gamma'$  by Clause (6), but it can vary freely over  $(\Gamma \times \Gamma) \setminus (\Gamma' \times \Gamma')$  since Clause (5) is vacuously satisfied by all structures. Therefore, the correct FOMC should be  $2^{|\Gamma|^2 - |\Gamma'|^2}$ . However, without line 9, **Propagate** would simplify  $\phi$  to  $\forall y, z \in \Gamma'. P(y, z)$ . In this case,  $P$  is a subset of  $\Gamma' \times \Gamma'$ . This simplified formula has only one model:  $\{P(y, z) \mid y, z \in \Gamma'\}$ . By including line 9, **Propagate** transforms  $\phi$  to

$$(\forall y, z \in \Gamma. P(y, z) \vee \neg P(y, z)) \wedge (\forall y, z \in \Gamma'. P(y, z)),$$

which retains the correct model count.

It is worth mentioning that the choice of  $l$  on line 8 of Algorithm 3 is inconsequential because any choice achieves the same goal: constructing a tautological clause that retains the literals in  $C'$ .

### 3.5 Generating C++ Code

In this section, we will describe the final step of GANTRY as outlined in Figure 1, i.e., translating the set of equations  $\mathcal{E}$  into C++ code. Recall that this step is crucial for the usability of the algorithm, otherwise function definitions would remain purely mathematical, with no convenient way to compute the model count for particular domain sizes. Once a C++ program is produced, it can be executed with different command-line arguments to compute the model count of the formula for various domain sizes.

See Algorithm 4 for the typical structure of a generated C++ program. Each equation in  $\mathcal{E}$  is compiled into a C++ function, along with a separate cache for memoisation. Hence, Algorithm 4 has a function and a cache for  $f(\cdot, \cdot)$ ,  $g(\cdot, \cdot)$ ,  $g(\cdot, 0)$ , and  $g(0, \cdot)$ . The implementation of an equation consists of three parts. First (on line 5), we check if the arguments are already present in the corresponding cache. If so, we simply return the cached value. Second (on lines 6 and 7), for each base case, we check if the arguments match the base case (as defined in Section 2.4). If so, the arguments are redirected to the C++ function for that base case. Finally, if none of the above cases apply, we evaluate the arguments based on the expression on the RHS of the equation, store the result in the cache, and return it.

## 4 Experimental Evaluation

Our empirical evaluation sought to compare the runtime performance of GANTRY with the current state of the art, namely FASTWFOMC and FORCLIFT. Our experiments involve two versions of GANTRY: GANTRY-GREEDY and GANTRY-BFS. Like its predecessor, GANTRY has two modes for applying compilation rules to formulas: one that uses a greedy search algorithm similar to FORCLIFT and another that combines greedy and BFS.

The experiments were conducted using an Intel Skylake 2.4 GHz CPU with 188 GiB of memory and CentOS 7. C++ programs were compiled using the Intel C++ Compiler 2020u4. FASTWFOMC ran on Julia 1.10.4, while the other algorithms were executed on the Java Virtual Machine 1.8.0\_201.

### 4.1 Benchmarks

- Make sure it's clear what the 'raw' instances are
- Don't emphasise that the benchmarks come from my previous work
- Integrate the example below into the text, possibly moving irrelevant details (such as the formulas in other logics) to supplementary material

We compare these algorithms using three benchmarks from previous studies. The first benchmark is the function-counting problem from Example 25, previously examined by Dilkas and Belle [6]. The second benchmark is a variant of the well-known 'Friends and Smokers' (hitherto referred to as 'friends') Markov logic network [20, 28]. In  $C^2$ , FO, and  $UFO^2 + CC$ , this problem can be formulated as

$$(\forall x, y \in \Delta. S(x) \wedge F(x, y) \Rightarrow S(y)) \wedge (\forall x \in \Delta. S(x) \Rightarrow C(x))$$

or, equivalently, in conjunctive normal form as

$$(\forall x, y \in \Delta. S(y) \vee \neg S(x) \vee \neg F(x, y)) \wedge (\forall x \in \Delta. C(x) \vee \neg S(x)).$$

Finally, we include the bijection-counting problem previously utilised by Dilkas and Belle [6]. Its formulation in FO is described in Example 2.

► **Example 25** (Counting functions). To define predicate  $P$  as a function from a domain  $\Delta$  to itself, in FO we would write

$$(\forall x \in \Gamma. \exists y \in \Delta. P(x, y)) \wedge (\forall x \in \Gamma. \forall y, z \in \Delta. P(x, y) \wedge P(x, z) \Rightarrow y = z). \quad (7)$$

The first clause asserts that each  $x$  must have at least one corresponding  $y$ , while the second statement adds the condition that if  $x$  is mapped to both  $y$  and  $z$ , then  $y$  must equal  $z$ . It is important to note that Formula (7) is written with two domains instead of just one. However, we can still determine the correct number of functions by assuming that the sizes of  $\Gamma$  and  $\Delta$  are equal. This formulation, as observed by Dilkas and Belle [6], can prove beneficial in enabling FOKC algorithms to find efficient solutions.

For each curve, check which polynomial or exponential model best fits the data to expand this section a bit (without plotting them, but describing the method).

The three benchmark families cover a wide range of possibilities. The 'friends' benchmark stands out as it uses multiple predicates and can be expressed in FO using just two variables without cardinality constraints or counting quantifiers. The 'functions' benchmark, on the

■ **Figure 2** The runtime of the algorithms as a function of the domain size. Note that both axes are on a logarithmic scale.

other hand, can still be handled by all the algorithms, but it requires cardinality constraints, counting quantifiers, or more than two variables. Lastly, the ‘bijections’ benchmark is an example of a formula that FASTWFOMC can handle but FORCLIFT cannot.

For evaluation purposes, we ran each algorithm on each benchmark using domains of sizes  $2^1, 2^2, 2^3$ , and so on, until an algorithm failed to handle a domain size due to timeout, out of memory error, or out of precision errors. While we separately measured compilation and inference time, we primarily focus on total runtime, dominated by the latter.

## 4.2 Results

- We are not aware of any formulas on which GANTRY scales worse compared to either FORCLIFT or FASTWFOMC. The one advantage that FASTWFOMC has over GANTRY is its support for counting quantifiers.
- Regarding programming languages and accuracy, we verified that the answers match for smaller domain sizes. Also, although written in different languages, both GANTRY and FASTWFOMC use the GNU Multiple Precision Arithmetic Library.

Incorporate into the text below: It is worth remarking that FORCLIFT does not support arbitrary precision, and returns error for cases that requires arbitrary precision reasoning.

Figure 2 presents a summary of the experimental results. Only FASTWFOMC and GANTRY-BFS could handle the bijection-counting problem. For this benchmark, the largest domain sizes these algorithms could accommodate were 64 and 4096, respectively. On the other two benchmarks, FORCLIFT had the lowest runtime. However, since it can only handle model counts smaller than  $2^{31}$ , it only scales up to domain sizes of 16 and 128 for ‘friends’ and ‘functions’, respectively. FASTWFOMC outperformed FORCLIFT in the case of ‘friends’, but not ‘functions’, as it could handle domains of size 1024 and 64, respectively. Furthermore, both GANTRY-BFS and GANTRY-GREEDY performed similarly on both benchmarks. Similarly to the ‘bijections’ benchmark, GANTRY significantly outperformed the other two algorithms, scaling up to domains of size 8192 and 67,108,864, respectively.

Another aspect of the experimental results that deserves separate discussion is compilation. Both Julia and Scala use just-in-time (JIT) compilation, which means that FASTWFOMC and FORCLIFT take longer to run on the smallest domain size, where most JIT compilation

occurs. In the case of GANTRY, it is only run once per benchmark, so the JIT compilation time is included in its overall runtime across all domain sizes. Additionally, while FORCLIFT's compilation is generally faster than that of GANTRY, neither significantly affects overall runtime. Specifically, FORCLIFT compilation typically takes around 0.5 s, while GANTRY compilation takes around 2.3 s.

Based on our experiments, which algorithm should be used in practice? If the formula can be handled by FORCLIFT and the domain sizes are reasonably small, FORCLIFT is likely the fastest algorithm. In other situations, GANTRY is expected to be significantly more efficient than FASTWFOMC regardless of domain size, provided both algorithms can handle the formula.

## 5 Conclusion and Future Work

In this work, we have presented a scalable automated FOKC-based approach to FOMC. Our algorithm involves completing the definitions of recursive functions and subsequently translating all function definitions into C++ code. Empirical results demonstrate that GANTRY can scale to larger domain sizes than FASTWFOMC while supporting a wider range of formulas than FORCLIFT. The ability to efficiently handle large domain sizes is particularly crucial in the weighted setting, as illustrated by the 'friends' example discussed in Section 4, where the model captures complex social networks with probabilistic relationships. Without this scalability, the practical usefulness of these models would be limited.

Future directions for research include conducting a comprehensive experimental comparison of FOMC algorithms to better understand their comparative performance across various formulas. The capabilities of GANTRY could also be characterised theoretically, e.g. by proving completeness for specific logic fragments like  $C^2$ . Additionally, the efficiency of FOMC algorithms can be further analysed using fine-grained complexity, which would provide more detailed insights into the computational demands of different formulas.

Logic	Sorts	Constants	Variables	Quantifiers	Additional atoms
FO	one or more	✓	unlimited	$\forall, \exists$	$x = y$
$C^2$	one	✗	two	$\forall, \exists, \exists^{=k}, \exists^{\leq k}, \exists^{\geq k}$	—
$UFO^2 + CC$	one	✗	two	$\forall$	$ P  = m$

■ **Table 1** A comparison of the three logics used in FOMC. The 2<sup>nd</sup>–5<sup>th</sup> columns refer to: the number of sorts, support for constants, the maximum number of variables, and supported quantifiers, respectively. The last column lists supported atoms in addition to those of the form  $P(\mathbf{t})$  for a predicate  $P/n$  and an  $n$ -tuple of terms  $\mathbf{t}$ . Here:  $k$  and  $m$  are non-negative integers, with the latter depending on the domain size,  $P$  represents a predicate, and  $x$  and  $y$  are terms.

## A The Three Logics of FOMC

- Reference the table
- Delete references to this appendix (except for one place, probably in Section 4)
- Make sure the rest of the paper doesn’t refer to these logics (or describe examples in them)
- Move the URLs to the main text
- Later (probably) move this to a different file

562 There are three first-order logics commonly used in FOMC: FO,  $C^2$ , and  $UFO^2 + CC$ .  
563 First, FO is the input format for FORCLIFT<sup>†</sup> and its extensions CRANE<sup>‡</sup> and GANTRY.  
564 Second,  $C^2$  is often used in the literature on FASTWFOMC<sup>§</sup> and related methods [12, 13].  
565 Finally,  $UFO^2 + CC$  is the input format supported by the most recent implementation of  
566 FASTWFOMC [23]. All three logics are function-free, and domains are always assumed  
567 to be finite. As usual, we presuppose the *unique name assumption*, which states that two  
568 constants are equal if and only if they are the same constant [18].

570 In FO, each term is assigned to a *sort*, and each predicate  $P/n$  is assigned to a sequence  
571 of  $n$  sorts. Each sort has its corresponding domain. These assignments to sorts are typically  
572 left implicit and can be reconstructed from the quantifiers. For example,  $\forall x, y \in \Delta. P(x, y)$   
573 implies that variables  $x$  and  $y$  have the same sort. On the other hand,  $\forall x \in \Delta. \forall y \in \Gamma. P(x, y)$   
574 implies that  $x$  and  $y$  have different sorts, and it would be improper to write, for example,  
575  $\forall x \in \Delta. \forall y \in \Gamma. P(x, y) \vee x = y$ . FO is also the only logic to support constants, formulas  
576 with more than two variables, and the equality predicate. While we do not explicitly refer to

<sup>†</sup> <https://github.com/UCLA-StarAI/Forclift>

<sup>‡</sup> <https://doi.org/10.5281/zenodo.8004077>

<sup>§</sup> <https://github.com/jan-toth/FastWFOMC.jl>

sorts in subsequent sections of this paper, the many-sorted nature of FO is paramount to the algorithms presented therein.

► **Remark.** In the case of FORCLIFT and its extensions, support for a formula as valid input does not imply that the algorithm can compile the formula into a circuit or graph suitable for lifted model counting. However, it is known that FORCLIFT compilation is guaranteed to succeed on any FO formula without constants and with at most two variables [27, 29].

Compared to FO,  $C^2$  and  $UFO^2 + CC$  lack support for constants, the equality predicate, multiple domains, and formulas with more than two variables. The advantage that  $C^2$  brings over FO is the inclusion of *counting quantifiers*. That is, alongside  $\forall$  and  $\exists$ ,  $C^2$  supports  $\exists^{=k}$ ,  $\exists^{\leq k}$ , and  $\exists^{\geq k}$  for any positive integer  $k$ . For example,  $\exists^{=1}x. \phi(x)$  means that there exists *exactly one*  $x$  such that  $\phi(x)$ , and  $\exists^{\leq 2}x. \phi(x)$  means that there exist *at most two* such  $x$ .  $UFO^2 + CC$ , on the other hand, does not support any existential quantifiers but instead incorporates (*equality*) *cardinality constraints*. For example,  $|P| = 3$  constrains all models to have *precisely three positive literals with the predicate P*.

## A.1 Our Benchmarks in $C^2$ and $UFO^2 + CC$

- An introductory paragraph
- Figure out the right order in which the information below should be presented
- Make the text below coherent
- Refer to it in the main text (and make sure the reference sticks when I transfer this to a separate file)

‘Friends’ in  $C^2$  and  $UFO^2 + CC$  is the same as in FO.

For ‘bijections’, the equivalent formula in  $C^2$  is

$$(\forall x \in \Delta. \exists^{=1}y \in \Delta. P(x, y)) \wedge (\forall y \in \Delta. \exists^{=1}x \in \Delta. P(x, y)).$$

Similarly, in  $UFO^2 + CC$  the same formula can be written as

$$(\forall x, y \in \Delta. R(x) \vee \neg P(x, y)) \wedge (\forall x, y \in \Delta. S(x) \vee \neg P(y, x)) \wedge (|P| = |\Delta|),$$

where  $w^-(R) = w^-(S) = -1$ .

For ‘functions’, in  $C^2$  one would write  $\forall x \in \Delta. \exists^{=1}y \in \Delta. P(x, y)$ . In  $UFO^2 + CC$ , the same could be written as

$$(\forall x, y \in \Delta. S(x) \vee \neg P(x, y)) \wedge (|P| = |\Delta|), \tag{8}$$

where  $w^-(S) = -1$ . Although Formula (8) has more models compared to its counterpart in  $C^2$ , the negative weight  $w^-(S) = -1$  makes some of the terms in Equation (2) cancel out.
